Abstract
Motivated by extremely large-scale machine learning problems, we introduce a new multi-stage algorithmic framework for submodular maximization (called MULTGREED), where at each stage we apply an approximate greedy procedure to maximize surrogate submodular functions. The surrogates serve as proxies for a target submodular function but require less memory and are easy to evaluate. We theoretically analyze the performance guarantee of the multi-stage framework and give examples on how to design instances of MULTGREED for a broad range of natural submodular functions. We show that MULTGREED performs very closely to the standard greedy algorithm given appropriate surrogate functions and argue how our framework can easily be integrated with distributive algorithms for further optimization. We complement our theory by empirically evaluating on several real-world problems, including data subset selection on millions of speech samples where MULTGREED yields at least a thousand times speedup and superior results over the state-of-the-art selection methods.

1 Introduction

Data sets are large and are getting larger. This, on the one hand, is useful as “there is no data like more data.” On the other hand, it presents challenges since the information in vast quantities of data may be difficult to ascertain simply due to the computational difficulties created by vastness itself. An important goal in machine learning and information retrieval, therefore, is to develop methods that can efficiently extract and summarize relevant and useful information in large data sets.

One recent class of methods gaining some prominence in machine learning is based on submodular functions for combinatorial selection. Traditionally studied in mathematics, economics, and operations research, submodular functions naturally occur in many real world machine learning applications. A submodular function (Fujishige, 2005) is a discrete set function \( f : 2^V \rightarrow \mathbb{R} \) that returns a real value for any subset \( S \subseteq V \), and satisfies \( f(A) + f(B) \geq f(A \cap B) + f(A \cup B), \forall A, B \subseteq V \). Equivalently, \( f \) satisfies the diminishing returns property, \( f(S) \geq f(T), \forall S \subseteq T, \) where \( f(S) = f(T) - f(S) \) is the gain of adding element \( j \) to set \( S \). A submodular function \( f \) is monotone non-decreasing if \( f(S) \geq 0, \forall j \in V \setminus S, S \subseteq V \), and \( f \) is normalized if \( f(\emptyset) = 0 \).

Submodular functions naturally measure the amount of information that lies within a given set \( A \subseteq V \), what is actually meant by “information” depends very much on the particular function. For example, given a collection of random variables \( X_1, X_2, \ldots, X_n \), where \( n = |V| \), the entropy function \( f(A) = H(\bigcup_{a \in A} X_a) \) is submodular. The rank of a subset \( A \) of columns of a matrix is also submodular and can be seen as representing information as the dimensionality of the vector space spanned by the vectors indexed by \( A \). There are other submodular functions that could represent “information” in some form (Fujishige, 2005; Kempe et al., 2003; Krause et al., 2008; Lin and Bilmes, 2011). Given a large collection of items \( V \) whose information content is \( f(V) \) where \( f \) is submodular, a natural and common optimization problem is:

\[
\max_{S \subseteq V, |S| \leq \ell} f(S).
\]  

Problem (1) asks for the most informative subset of items of size \( \ell \) or less. This problem has already found great utility in a number of areas in machine learning, including document summarization (Lin and Bilmes, 2011), speech data subset selection (Wei et al., 2013), feature subset selection (Krause and Guestrin, 2005a; Liu et al., 2013), social influence (Kempe et al., 2003), and sensor placement (Krause et al., 2008). Though the problems are NP-hard, a well-known result by Nemhauser et al. (Nemhauser et al., 1978) shows that Problem 1 can be solved near-optimally by a simple greedy algorithm with a worst case approximation.
factor of $1 - 1/e$. Moreover, (Feige, 1998) shows that this is tight unless P=NP. In this paper, we shall refer to the solution of the greedy algorithm, though approximate, as the optimum solution for simplicity. The greedy algorithm starts with the empty set $S_0 = \emptyset$. In each iteration $i$, it identifies the element $s_i$ that maximizes the marginal gain $f(s_i | S_{i-1})$ (i.e., $s_i \in \arg\max_{s \in V \setminus S_{i-1}} f(e | S_{i-1})$) with ties broken arbitrarily and updates as $S_i \leftarrow S_{i-1} \cup \{s_i\}$. Submodularity can be further exploited to accelerate (Minoux, 1978) this greedy algorithm – a procedure often called the “accelerated” or “lazy” greedy algorithm (LazyGreed) (Leskovec et al., 2007).

In many cases, the very advanced machine learning algorithms that we need to use to process large data sources are too computationally costly for the amount of data that exists. For example, when the data source is very large (e.g., $n$ in the billions or trillions), even LazyGreed becomes untenable. Moreover, even smaller sized $n$ can be prohibitive, particularly when evaluating the function $f$ itself is expensive. For example, in document summarization (Lin and Bilmes, 2011) and speech data subset selection (Wei et al., 2013) certain submodular functions (which we call graph-based), are often defined via a pair-wise similarity graph, having a time and memory complexity of $O(n^2)$. This is infeasible even for medium-scale values of $n$. Another application is the feature selection (Krause and Guestrin, 2005a; Iyer and Bilmes, 2012; Liu et al., 2013), where a common objective is to maximize the mutual information between a given set of random variables $X_A$ and a class $C$ (i.e $I(X_A; C)$). The mutual information depends on computing the entropy $H(X_A)$ which can be expensive (or even exponential cost) to evaluate. Similarly, the recent promising work on determinantal point processes (DPPs) (Kulesza and Taskar, 2012), where one wants to maximize the submodular function $f(A) = \log \det(S_A)$ for a given matrix $S$, becomes problematic since computing log-determinant can require an $O(n^3)$ computation which is impractical already on medium-sized data sets.

We therefore ask the question: are there other approaches that can address Problems (1) and that are scalable to very large data sets, and that still offer theoretical guarantees?

Related Work: Parallel computing approaches are of course a natural pursuit for solving large-scale algorithmic challenges, and some instances of distributed algorithms for submodular optimization have already been investigated. For example, (Chierichetti et al., 2010) propose a distributed algorithm to solve Problem 1 with the set cover function as the objective, and with an approximation factor of $1 - 1/e - \epsilon$. Similarly, Kumar et al., 2013) propose a distributed algorithm to solve Problem 1 with any submodular objective and with an approximation factor of $1/2 - \epsilon$. Motivated by the difficulty of rendering the entire data set centrally for function evaluation, (Mirzasoleiman et al., 2013) propose a two-stage algorithmic framework to solve Problem 1 with an approximation factor of $O(\frac{1}{\min\{\ell,m\}})$, where $\ell$ and $m$ are the cardinality constraint and the number of distributed partitions, respectively. The performance guarantee can be improved to be close to optimum if the data set is massive and satisfies certain geometric assumptions. All these algorithms can be implemented in a Map-Reduce style.

Our Contributions: In this work, we propose a multi-stage framework (MultGreed) that directly addresses the time and memory complexity issues of running LazyGreed in three ways: (a) reducing the number of function evaluations required for the algorithm, (b) decreasing the complexity of function evaluations by using simpler surrogate (proxy) functions, (c) reducing the ground set size. Though quite different in spirit from the distributive framework, our approach could easily be performed in concert with existing distributed algorithms. For instance, we can apply MultGreed instead of LazyGreed for solving each sub-problem in (Mirzasoleiman et al., 2013). Conversely, their distributed procedure could also be used to solve the sub-problem in each stage of MultGreed. The theoretical analysis for both frameworks could easily be combined with each other, and they could be integrated to provide still more efficient large-scale algorithmic frameworks for these problems. Hence, our approach is complementary to the existing distributive architectures, although in the present paper we will concentrate on our novel multi-stage uni-processor approach.

Outline Section 2 gives an overview of our framework. In Section 3, we theoretically analyze its performance while Section 4 offers several choices of surrogate functions for certain practical and useful classes of submodular functions. In Section 5, we focus on the design of MultGreed on a broad range of submodular functions, and instantiate our general framework for several submodular functions, thereby providing recipes for many real-world problems. In Section 6, we empirically demonstrate the performance of MultGreed, where we apply MultGreed to a large-scale speech data subset selection problem and show that it yields superior results over the state-of-the-art selection methods.

2 Multi-Stage Algorithmic Framework

Often in applications, there is a desirable in quality but prohibitive in computational complexity submodular function that we shall refer to as the target function $f$. We assume a ground set size of $n = |V|$, a cardinality constraint of $\ell$, and that the optimal solution to Problem (1) is $S_{\text{OPT}}$.

For completeness, we first describe how LazyGreed
accelerates the naïve greedy implementation. The key insight is that the marginal gain of any element \( v \in V \) is non-increasing during the greedy algorithm (a consequence of the submodularity of \( f \)). Instead of recomputing \( f(v|S_{i-1}) \) for each \( v \), the accelerated greedy algorithm maintains a list of upper bounds \( \rho(v) \) on each item's current marginal gain. They are initialized as \( \rho(v) \leftarrow f(v) \) for each \( v \in V \), and sorted in decreasing order (implemented as a priority queue). In iteration \( i \), the algorithm pops the element \( v \) off the top of the priority queue and updates the bound \( \rho(v) \leftarrow f(v|S_i) \). \( v \) is selected if \( \rho(v) \geq \rho(u) \), where \( u \) is at the current top of the priority queue, since submodularity in such case guarantees that \( v \) provides the maximal marginal gain. Otherwise, we appropriately place the updated \( \rho(v) \) back in the priority queue and repeat.

To this end, we consider three schemes to further accelerate \textsc{LazyGreed}: (a) reduce the number of function evaluations (Approximate greedy), (b) reduce the complexity of function evaluations (using simpler proxy functions), (c) reduce the ground set size (Pruning). This ultimately leads to our multi-stage greedy framework \textsc{MultiGreed}.

**Approximate greedy:** In this part, we introduce a mechanism called \textsc{ApproxFastGreed}, to reduce the number of function evaluations in \textsc{LazyGreed}. We give a theoretical analysis for \textsc{ApproxFastGreed} in Section 3 — the current section defines and then offers intuition for the method. The key idea of \textsc{ApproxFastGreed} is that it does not insist on finding the item that attains exactly the maximum marginal gain in each iteration, but instead, looks for an item whose marginal gain is close to this maximum. \textsc{ApproxFastGreed} only modifies \textsc{LazyGreed} by weakening the selection criteria in each iteration. More formally, if an item \( v \) is selected by \textsc{LazyGreed}, the optimality of its marginal gain is guaranteed if the \textit{exact condition} \( \rho(v) \geq \rho(u) \) (\( u \) is the current top of the priority queue) is met. \textsc{ApproxFastGreed} relaxes this to an \textit{approximate condition} \( \rho(v) \geq \beta \rho(u) \), where \( 0 < \beta < 1 \). Since a potentially large number of items' marginal gains need to be reevaluated until the exact condition is met, using the approximate condition could effectively reduce the number of function evaluations at a loss of the original guarantee. The parameter \( \beta \) controls the level of sub-optimality: the smaller \( \beta \), the number of function evaluations reduces as does the performance guarantee. In other words, \textsc{ApproxFastGreed}, as an approximate scheme to \textsc{LazyGreed}, has its performance guarantee carried over from that of \textsc{LazyGreed}, with an additional level of approximation governed by the value \( \beta \) (the formal guarantee of \((1 - e^{-\beta})\) is given in Lemma 2). We would like to point out the resemblance of \textsc{ApproxFastGreed} to the recently proposed fast greedy algorithm for Problem 1 (Badanidiyuru and Vondrák, 2014). Similar to \textsc{ApproxFastGreed}, they seek to identify an item whose marginal gain is within a fraction \( \beta \) of the maximum marginal gain in each iteration and yield the an approximation factor of \((1 - e^{-\beta})\). Unlike their algorithm, \textsc{ApproxFastGreed} builds on top of the \textsc{LazyGreed}, hence, further exploits the submodularity. Though quite similar in spirit, \textsc{ApproxFastGreed} might run significantly faster, in practice, than their algorithm, while yielding the same performance guarantee.

\textsc{ApproxFastGreed} is only a minor modification of an existing \textsc{LazyGreed} implementation and thus does not extend to other algorithms for Problem 1.

\textsc{ApproxFastGreed} can be further generalized by setting the value of \( \beta \) individually for each iteration, i.e., a sequence \( \{\beta_i\}_{i=1} \). Intuitively, we would design \( \{\beta_i\}_{i=1} \) to be non-decreasing, i.e., the allowed sub-optimality decreases as the algorithm proceeds. The reason for this is that a less accurate selection at the begin has a chance of being corrected by more accurate selection in later iterations. One possible schedule would be \( \beta_i = c + \frac{1}{L}(i-1) \), where \( c < 1 \) determines the initial sub-optimality degree of the algorithm. Then, \( \beta_i \) grows linearly in \( i \) from \( c \) to \( 1 \), and the choice of \( c \) determines the trade-off between the running time reduction and performance guarantee loss. Given \( f \), \( \ell \), and \( \{\beta_i\}_{i=1} \), we shall instantiate the approximate greedy procedure as \( S \in \text{ApproxFastGreed}(f, \ell, \{\beta_i\}_{i=1}) \).

**Multi-stage framework:** \textsc{ApproxFastGreed} yields effective reduction on the number of function evaluations in \textsc{LazyGreed}, however, the complexity of each function evaluation could still be so high that the greedy procedure is rendered impractical. To address this issue, we propose an approach, \textsc{MultiGreed}, that utilizes classes of simple surrogate functions which could be applied to a broad range of submodular functions. The idea is to optimize a series of surrogate (proxy) functions instead of optimizing the target function \( f \).

**Algorithm 1** \textsc{MultiGreed}: A Multi-Stage Greedy Alg.

Input \( f, \ell, J, \{f_j\}_{j=1} \), \( \{\ell_j\}_{j=1} \), \( \{\beta_i\}_{i=1} \)

\( C \leftarrow \emptyset \), \( L \leftarrow 0 \)

for \( j = 1 \ldots J \) do

\[ \text{Define } F_j(S) \triangleq f_j(S|C) \text{ for all } S \subseteq V \]

\[ S \in \text{ApproxFastGreed}(F_j, \ell_j, \{\beta_i\}_{i=L+\ell_j}) \]

\[ L = L + \ell_j, \quad C \leftarrow C \cup S \]

Output \( C \)

Given a sequence \( \{\beta_i\}_{i=1} \), a set of cardinality constraints \( \{\ell_1, \ldots, \ell_J\} \) such that \( \sum_{j=1}^J \ell_j = \ell \) and \( \ell_j > 0, \forall j \), and a corresponding set of \( J \) surrogate (proxy) submodular functions \( \{f_j\}_{j=1} \), we define our framework \textsc{MultiGreed} as shown in Algorithm 1. The series of the surrogate functions should be designed in increasing order of complexity, and at the last stage of \textsc{MultiGreed}, \( f_J \) can even be the target function \( f \). The
algorithm should typically start with a computationally simple surrogate submodular function $f_1$ (which could even be modular). Since the surrogate functions $f_j$ are designed to be computationally cheaper than the target function $f$, and since APPROXGREED is applied instead of LAZYGREED in each stage, we are guaranteed to achieve an overall reduction in computation. In practice (see Section 5 and 6), we often observe an instance of MULTGREED with $J = 2$ suffices to yield good enough performance and complexity reduction as well, though our results are much more general.

**Pruning:** In addition to the above two schemes, it is also desirable to prune out items of the ground set that will never be chosen anyway, especially for large-scale data set. This is commonly done for submodular minimization (Fujishige, 2005; Iyer et al., 2013b). Arbitrary pruning procedures, however, can significantly weaken the theoretical guarantee for Problem 1. We introduce here a simple new method that can prune away items without a corresponding performance loss. Consider the sequence of items $\{u_1, \ldots, u_n\}$ ordered non-increasingly in terms of their gain conditioned on all other items, i.e., $f(u_1|V \setminus u_1) \geq \cdots \geq f(u_n|V \setminus u_n)$. For an instance of Problem 1 with cardinality constraint $\ell$, we have the following Lemma:

**Lemma 1.** LAZYGREED applied on the reduced ground set $\tilde{V} = \{ j \in V | f(j) \geq f(u_1|V \setminus u_1) \}$ is equivalent to that applied to the ground set $V$.

The proofs for all the results in this paper are deferred to Appendix. This procedure can easily be implemented in parallel, since $f(j)$ and $f(j|V \setminus j)$ can be computed independently for all $j \in V$. The pruning procedure is optional and is applicable only when the complexity of evaluating $f(u|V \setminus u)$ is no greater than that of $f(u)$. This is the case, for example, in our graph-based submodular functions. It is not true, however, for the entropy-based functions, nor the log-determinant style functions. Otherwise, the complexity of the pruning procedure could potentially even dominate that of LAZYGREED, rendering it useless. MULTGREED may optionally start with this ground set pruning step, but it does not influence our analysis.

Our analysis of Algorithm 1 is given in Section 3, while in Section 4, we illustrate examples on how to design surrogate functions. In Section 5, we shall instantiate our framework and provide recipes for choosing the parameters of MULTGREED for several submodular functions which occur as models in real world applications.

### 3 Analysis

In this section, we formally analyze the methods presented in Section 2. We first define several crucial constructs that will facilitate this analysis.

**Greedy ratio:** We define a new construct we call the greedy ratio that will quantify the performance of a given instance of MULTGREED, which is characterized by the parameters: $\{ f_j \}_{j=1}^J$, $\{ \ell_j \}_{j=1}^J$, $\{ \beta_j \}_{j=1}^J$. Guidelines on how to design the parameters of the multi-stage framework for several natural instances of useful submodular functions are given in Sections 4 and 5, but for now assume they are given. Let $s_1, \ldots, s_\ell$ be the sequence of items selected by the instance of MULTGREED. Let $S_1 = \{s_1, \ldots, s_1\}$ be a set element of the chain $S_1 \subset S_2 \subset \cdots \subset S_\ell$, with $S_0 = \emptyset$.

Define the individual greedy ratio $\alpha_i$ for $i = 1, \ldots, \ell$ as:

$$\alpha_i = \frac{\max_{u \in V} f(u|S_{i-1})}{f(s_i|S_{i-1})}$$

Each $\alpha_i$ captures the ratio of the marginal gain of the greedily selected element to the marginal gain of the element $s_i$ selected by MULTGREED. Therefore, $\alpha_i$ is a function of both the target function $f$ but also, indirectly via ordered list $(s_1, s_2, \ldots, s_\ell)$, all of the remaining parameters $\{ f_j \}_{j=1}^J$, $\{ \ell_j \}_{j=1}^J$, $\{ \beta_j \}_{j=1}^J$. Also, since $\max_{u \in V} f(u|S_{i-1}) \geq f(s_i|S_{i-1})$, we have that $\alpha_i \geq 1, \forall i$. Moreover, since under APPROXGREED we have $f(s_i|S_{i-1}) \geq \beta_i f(u|S_{i-1})$ for all $u \in V \setminus S_{i-1}$, it follows that $\alpha_i \leq 1/\beta_i$ for each $i$.

The list $\{ \alpha_i \}_{i=1}^\ell$ collectively measures the quality of the multi-stage framework. We therefore define the greedy ratio $\alpha$ to be an aggregation of the individual greedy ratios. While there are many ways of aggregating, the harmonic mean, as we will show, provides the tightest characterization. We thus define the greedy ratio $\alpha$ as:

$$\alpha = \frac{\ell}{\sum_{i=1}^\ell 1/\alpha_i}$$

The greedy ratio, as we shall see, will provide a tight approximation guarantee. Ideally, we would like to have each individual greedy ratio $\alpha_i = 1$ for all $i$, and thus a greedy ratio of $\alpha = 1$. In particular, our strategy for choosing surrogate functions and other parameters is to induce a greedy ratio that is as small as possible.

**Curvature:** Another important construct we shall need is the curvature. Given a submodular function $f$, we define $\kappa_f(S)$ as the curvature of $f$ with respect to a set $S$ as follows:

$$\kappa_f(S) = 1 - \min_{v \in V} \frac{f(v|S \setminus v)}{f(v)}$$

$\kappa_f(S)$ lies in the range of $[0, 1]$, and is monotonically non-decreasing in $S$. It measures the distance of $f$ from modularity and $\kappa_f = 0$ if and only if $f$ is modular (or additive, i.e., $f(S) = \sum_{i \in S} f(i)$). The total curvature (Conforti and Cornuejols, 1984) $\kappa_f$ is then $\kappa_f(V)$. A number of approximation guarantees for submodular optimization are improved when using...
Conversely, for any value of \( c \) (c.f. Section 2), we have \( \bar{f} \) curvature to obtain a set \( S \) s.t.

\[
\frac{f(S)}{f(S^{OPT})} \geq \frac{1}{\kappa_f} (1 - (1 - \frac{1}{\alpha})^\ell) \geq \frac{1}{\kappa_f} (1 - e^{-\frac{\alpha}{\ell}}) \\
\geq (1 - e^{-\frac{\alpha}{\ell}}).
\]

Conversely, for any value of \( \alpha \geq 1 \) and \( \kappa_f \in [0, 1] \), there exists a submodular \( f \) with the total curvature \( \kappa_f \), on which an instance of \( \text{MULTGREED} \) with the greedy ratio \( \alpha \) achieves an approximation factor \( \frac{1}{\kappa_f} (1 - (1 - \frac{1}{\alpha})^\ell) \).

Theorem 1 states that \( \text{MULTGREED} \)’s guarantee is quantified tightly by the greedy ratio \( \alpha \). Moreover, the bound is, indirectly via \( \alpha \), dependent on all the parameters \( \{f_i\}_{i=1}^K \), \( \{\ell_i\}_{i=1}^K \), \( \{\beta_i\}_{i=1}^K \) of \( \text{MULTGREED} \). Theorem 1 generalizes bound \( \frac{1}{\kappa_f} (1 - e^{-\alpha}) \) (Conforti and Cornuejols, 1984) when \( \alpha = 1 \). By accounting for curvature, the bound \( \frac{1}{\kappa_f} (1 - e^{-\alpha}) \) itself generalizes the well-known result of \( 1 - 1/e \) for \( \text{LAZYGREED} \) on Problem 1. Also, as an immediate corollary of Theorem 1, we obtain the theoretical guarantee for \( \text{APPROXGREED} \) in terms \( \{\beta_i\}_{i=1}^K \).

**Lemma 2.** Given a submodular function \( f \) with total curvature \( \kappa_f \), \( \text{APPROXGREED} \{f, \ell, \{\beta_i\}_{i=1}^\ell\} \) is guaranteed to obtain a set \( S_i \): (here \( \beta = 1/\ell \sum_{i=1}^\ell \beta_i \))

\[
\frac{f(S_i)}{f(S^{OPT})} \geq \frac{1}{\kappa_f} (1 - (1 - \frac{\beta}{\ell})^\ell) \geq \frac{1}{\kappa_f} (1 - e^{-\kappa_f^{\beta}}) \geq (1 - e^{-\beta}),
\]

If the \( \{\beta_i\}_{i=1}^\ell \) are set as \( \beta_i = \epsilon i \) with \( 0 \leq \epsilon \leq 1 \) (c.f. Section 2), we have \( \beta \geq \frac{\beta}{\ell} \geq \frac{1}{2} \). Hence, this choice endows \( \text{APPROXGREED} \) with a solution having a factor no worse than \( 1 - e^{-1/2} \approx 0.39 \).

The performance loss in \( \text{MULTGREED} \) comes from two sources, namely the approximate greedy procedure and the surrogate functions. To simplify our analysis, we henceforth utilize only the exact greedy algorithm, \( (\forall i, \beta_i = 1) \). It should be clear, however, that our results will immediately generalize to the approximate greedy case as well.

The greedy ratio \( \alpha \) is the harmonic mean of the values \( \{\alpha_i\}_{i=1}^\ell \) that themselves can be partitioned into \( J \) blocks based on the \( J \) stages of \( \text{MULTGREED} \). For \( j = 1, \ldots, J \), define \( L_j = \sum_{j'=1}^j \ell_j' \), and let \( L_j = \{l_j - 1 + 1, l_j - 1 + 2, \ldots, L_j\} \) be the set of \( \ell_j \) indices for the \( j \)th block. Each stage \( j \) provides a bound on the greedy ratio since \( \alpha \leq \ell / \sum_{i \in L_j} 1/\alpha_i \). As a particularly simple example, if the target function \( f \) itself were to be utilized as the surrogate in the \( j \)th stage for \( \ell_j \) items, then each corresponding greedy ratio has value \( \alpha_i = 1 \) leading to the bound \( \alpha \leq \ell_j / \ell_j \). Therefore, from the perspective of this upper bound, one is afforded the opportunity to design each stage semi-independently. On the other hand, to achieve a given desired \( \alpha \), it is not possible to design the stages entirely independently since the individual greedy ratios interact within the harmonic mean.

**Generalization to knapsack constraint:** Besides its flexibility in giving theoretical analysis of \( \text{MULTGREED} \), the greedy ratio can work in a broader scenario. Consider a more general formulation of Problem 1 as:

\[
\max_{c(S) \leq B, S \subseteq V} f(S)
\]

where \( c(S) = \sum_{v \in S} c(v) \) with \( c(v) \geq 0 \) being the cost of \( v \in V \) and \( B \) is the budget constraint. Note many problems in machine learning applications, including sensor placement (Leskovec et al., 2007), document summarization (Lin and Bilmes, 2011), social networks (Singer, 2012) and training data subset selection (Wei et al., 2013), are formulated in this form. \( \text{LAZYGREED} \) for the cardinality constraint can be slightly modified to an algorithm, which we call \( \text{knapsack greedy algorithm} \), to solve Problem 5 with factor \( 1/(1 - e^{-1}) \) (Krause and Guestrin, 2005b). Another variant of the greedy algorithm (Sviridenko, 2004) that achieves tight approximation factor \( 1 - e^{-1} \) is not considered here, since its naive implementation requires \( O(n^3) \) oracle access. The knapsack greedy algorithm differs from \( \text{LAZYGREED} \) in two aspects: (a) it, in each iteration, greedily selects the element that maximizes the marginal gain normalized by its cost, i.e., finding \( s_i \in \arg\max_{u \in V \setminus s_{i-1}} \frac{f(u|s_{i-1})}{c(u)} \); (b) it compares the final solution of the greedy algorithm with the maximum singleton value with cost under the budget constraint \( B \), i.e., \( \max_{c(v) \leq B} (f(c), v) \), and outputs the maximum of the two. The multi-stage framework designed to solve Problem 1 can be adapted to incorporate the above two modifications and applied to Problem 5. Assume an instance of the multi-stage procedure stops at iteration \( N \), we denote the chain of items selected as \( \{s_1, \ldots, s_N\} \), with \( S_i = \{s_1, \ldots, s_i\} \) for \( i = 1, \ldots, N \). We generalize the definition of the individual greedy ratio as:

\[
\alpha_i = \frac{\max_{u \in V \setminus s_{i-1}} \frac{f(u|s_{i-1})}{c(u)}}{f(s_i|s_{i-1})/c(s_i)}
\]

for \( i = 1, \ldots, N \). And define the **knapsack greedy ratio** as

\[
\alpha = \frac{B'}{\sum_{j=1}^N c(s_j)/\alpha_j}
\]
where $B' = \sum_{i=1}^{N} c(s_i)$. It is worth pointing out the previously defined greedy ratio is a special case of the knapsack greedy ratio, where $c(v) = 1$ for $v \in V$.

**Theorem 2.** Given a target submodular function $f$, an instance of MULTGREED with knapsack greedy ratio $\alpha$ is guaranteed to obtain a set $S$ s.t.

$$f(S) \geq \frac{1}{2} (1 - e^{-\frac{1}{2}}) f(S^{OPT})$$

where $S^{OPT} \in \text{argmax}_{S \subseteq V, c(S) \leq B} f(S)$.

Theorem 2 generalizes the approximation factor $\frac{1}{2} (1 - e^{-1})$ (Krause and Guestrin, 2005b) where the knapsack greedy ratio is 1.

**Generalization to submodular set cover problem:** Closely related to Problem 5, the submodular set cover problem (Wolsey, 1982) is formulated as:

$$\min_{f(S) \geq f(V), S \subseteq V} c(S)$$

where $f$ is a monotone submodular function and the same as before, $c(S) = \sum_{v \in S} c(v)$ with $c(v) \geq 0$ being the cost of item $v$. The same knapsack greedy algorithm solves Problem 9 with log factor approximation guarantee (Wolsey, 1982). Therefore, the same multi-stage greedy framework that solves Problem 5 can be carried over to solve Problem 9. Given the observation that Problem 5 and 9 are duals of each other in that solution for one problem can be efficiently transformed to a solution for the other with bi-criterion approximation guarantee (Iyer and Bilmes, 2013), we obtain the following result.

**Theorem 3.** An instance of MULTGREED that solves Problem 5 with the knapsack greedy ratio $\alpha$ returns a solution that can be transformed to a solution $S$ for Problem 9 such that

$$c(S) \leq c(S^{OPT}) \text{ and } f(S) \geq \frac{1}{2} (1 - e^{-\frac{1}{2}}) f(V)$$

where $S^{OPT} \in \text{argmax}_{S \subseteq V, f(S) \geq f(V)} c(S)$

The solution only satisfies approximate feasibility to Problem 9. Theorem 3 shows that an instance of the multi-stage knapsack greedy algorithm provides constant factor bi-criterion approximation guarantee, although Problem 9 does not admit any constant-factor approximation algorithms (Feige, 1998).

**4 Surrogate Functions**

In this section, we investigate the interplay between the greedy ratio and several choices of surrogate functions for classes of submodular functions which appear often in practice. Since providing bounds on the performance of each stage individually implies an upper bound on the greedy ratio, we shall restrict ourselves to the analysis of the surrogate function at a given stage $j$, and the final performance guarantee is easily obtained by combining the guarantees for the different stages.

**Uniform Submodular Mixtures:** We first consider a class of submodular functions that can be represented as $f(S) = \frac{1}{|T|} \sum_{t \in T} f_t(S)$, where $|T| > 1$, and $f_t$ is monotone submodular $\forall t \in T$. We name this class *uniform submodular mixtures* as they are similar to the submodular mixtures previously defined in the context of learning (Lin and Bilmes, 2012). They are also similar to the *decomposable* submodular functions of (Stobbe and Krause, 2010) but without the requirement that $f_t(S)$ be a non-decreasing concave function composed with a non-negative modular function. A number of natural submodular functions belong to this class.

The complexity of evaluating $f$ is determined both by $|T|$ and the complexity of evaluating individual $f_t$’s. Given such an $f$, a natural class of random surrogates takes the form

$$\hat{f}_{\text{sub}}(S) = \frac{1}{|T'|} \sum_{t \in T'} f_t(S),$$

where $T' \subseteq T$, and $T'$ is generated by sampling individual elements from $T$ with probability $p$. As $p$ decreases, so does the complexity of evaluating $\hat{f}_{\text{sub}}$ but at the cost of a worse approximation to $f$. Applying a random function $\hat{f}_{\text{sub}}$ derived in this way to MULTGREED, and assuming $|f_t(S)| \leq B, \forall t \in T, S \subseteq V$, we obtain:

**Lemma 3.** Using the surrogate uniform mixture $\hat{f}_{\text{sub}}$ for stage $j$ in MULTGREED gives individual greedy ratios of

$$1 \leq \alpha_i \leq \frac{1}{1 - \epsilon}, \forall i \in I_j,$$

with probability $1 - \delta$, where $\delta = (1 - n^\epsilon e^{-\frac{\log n}{\epsilon s^2}})$ and $g^t = \max_{u \in V \setminus S_{t-1}} f(u|S_{t-1}) > 0$.

Fixing $\delta$, a smaller value of probability $p$ yields a higher value of $\epsilon$, weakening the bound on each $\alpha_i$. Fixing both $\delta$ and $\epsilon$, increases in the ground set size $n = |V|$ could yield a choice of surrogate function $\hat{f}_{\text{sub}}$ having a smaller sampling probability $p$ and thus that is easier to evaluate. More importantly, fixing $\delta$ and $p$, $\epsilon$ can be made arbitrarily close to 0 for $n$ sufficiently large, a result that is of great interest for very large-scale problems. We shall use this result to provide bounds for several instances of submodular functions in Section 5.

**Modular Upper bounds:** We next focus on a class of surrogate functions applicable to general submodular functions. Given a submodular function $f$, its simple
modular upper bound is given as

\[ f_{\text{mod}}(S) = \sum_{s \in S} f(s). \]  

(13)

For some submodular functions such as entropy (including Gaussian entropy and the log det functions used for DPPs) or mutual information, evaluating \( f_{\text{mod}}(S) \) is easy, while evaluating \( f(S) \) might sometimes even require computation exponential in \(|S|\). Though extremely simple, this class nevertheless can act as an efficient class of surrogate functions especially useful when the target function is not very curved. \( f_{\text{mod}} \) is not only easy to optimize exactly, but it has previously been considered as a surrogate for various other forms of submodular optimization curvature-submodular, rkiye-semiframework2013, rkiye-submodBregman2012. The curvature \( \kappa_f \), by definition, measures how close \( f \) is to being modular. If a modular surrogate function \( f_{\text{mod}} \), for general submodular function \( f \), is applied within MULTGREED, we can thus bound the individual greedy ratio via the curvature:

**Lemma 4.** Using the modular upper bound as a surrogate function, it holds that

\[ 1 \leq \alpha_i \leq \frac{1}{1 - \kappa_f(S_{i-1})}, \forall i \in I_j \]

Unsurprisingly, we see that the less curved the target function \( f \) is, the tighter bound on \( \alpha_i \)'s, and the better \( f_{\text{mod}} \) performs as a surrogate. In particular, if \( f \) is modular, i.e., \( \kappa_f = 0 \), then, all individual greedy ratio \( \alpha_i \)'s are tightly bounded as 1. Lemma 4 also implies that the bound of the individual greedy ratio weakens as \( i \) increases, since \( \frac{1}{1 - \kappa_f(S_{i-1})} \) increases with \( i \). Therefore, this modular proxy, if applied, is best done in the first (or at most early) stages of MULTGREED.

**Graph based Submodular functions:** We focus next on a class of submodular functions based on an underlying weighted graph and hence called graph-based. Many submodular functions used in machine learning applications belong to this class (Kolmogorov and Zabih, 2004; Wei et al., 2013; Liu et al., 2013; Lin and Bilmes, 2011). These functions require \( O(n^2) \) time to compute and store, which is not feasible for large \( n \).

To form surrogates for the class of graph-based submodular functions, a natural choice is to utilize spanning subgraphs of the original graph. One choice is the \( k \)-nearest neighbor graph (\( k \)-NNG), defined as the spanning subgraph formed with each vertex \( v \in V \) connected only to its \( k \) most similar neighbors (under the similarity score given by the edge weights). \( k \)-NNG has found great utilities in many machine learning applications (Shah et al., 2011; Boiman et al., 2008). We write \( \hat{f}_{k\text{-NNG}} \) as the surrogate function defined on a \( k \)-NNG for a graph-based submodular function \( f \). The sparsity of the \( k \)-NNG depends on the value of \( k \). The denser the graph (higher \( k \)), the costlier both the function evaluations and the memory complexity becomes. In Section 5, surprisingly we will show that \( \hat{f}_{k\text{-NNG}} \), even for \( k \) as sparse as \( O(\log n) \), can be good enough for certain graph-based functions.

5 Instantiations with Real World Submodular functions

Given the previously defined machinery to analyze MULTGREED, we now focus on a broad range of submodular functions that appear as models in real world applications, and provide guidelines on how to design the surrogate functions as well as how to choose the size constraints. We investigate the following special cases: 1) the facility location function, 2) saturated coverage function, 3) feature based function, 4) the set cover function. We focus on analyzing the theoretical guarantees for these functions here and demonstrate the performance of some of these empirically in the next section.

**Facility location function:** Given a weighted graph \( G = (V, E) \), with \( w_{u,v} \) the edge weight (i.e., similarity score) between vertices \( u \) and \( v \) for \( u, v \in V \), the (un capacitated) facility location function is defined as

\[ f_{\text{fac}} = \sum_{v \in V} \max_{u \in S} w_{u,v}. \]  

(14)

Define \( \hat{w} \) as \( k \)-NNG counterpart of \( w \), i.e., \( \hat{w}_{i,j} = w_{i,j} \) if \( j \) is among the \( k \) nearest neighbor of \( i \), and \( \hat{w}_{i,j} = 0 \), otherwise. To establish that \( \hat{f}_{k\text{-NNG}} \) is good even with very sparse \( k \), we rely on a key observation: \( \max_{j \in S} w_{i,j} = \max_{j \in S} \hat{w}_{i,j} \) holds if the set \( S \) contains at least one item that is among the \( k \) nearest neighbor of \( i \). Thus, showing that \( \hat{f}_{k\text{-NNG}}(S) \) is equivalent as showing that the set \( S \) contains at least one item that is among the \( k \) nearest neighbor of \( i \). Let's denote \( \hat{w}_i = \{ w_{i,1}, \ldots, w_{i,n} \} \) as the vector containing the weights on all edges out of the vertex \( i \). To this end, we assume that the ranking of any item \( j \in V \) among the vector \( \hat{w}_i \) for any \( i \in V \) is uniformly distributed over \( \{1, 2, \ldots, n \} \) and that the ranking of \( j \) in one weight vector \( \hat{w}_i \) is independent of its ranking in another.

**Lemma 5.** For the facility location function, we have:

\[ \hat{f}_{\text{fac}}(S) = f_{\text{fac}}(S), \forall S \subseteq V \text{ s.t. } |S| \geq m, \]  

(15)

with probability at least \( (1 - \theta) \), and the sparsity of the \( k \)-NNG being at least

\[ k = n[1 - (\frac{\theta}{n})^\frac{1}{m}]. \]  

(16)
Assuming that \( m, n \) are in the same order and that \( \theta \) is a constant, we have \( \lim_{n \to \infty} n \left[ 1 - \left( \frac{\theta}{n} \right)^{\frac{1}{n}} \right] = O(\log n) \). The lemma implies that with high probability, \( f^\text{fac} \) and \( f^\text{fac} \) share the same function value for any sets of size greater than some threshold \( m \), where the \( k \)-NNG can be as sparse as \( k = O(\log n) \). Note that the result does not extend to general graph-based submodular functions. However, the class of facility location functions, for various applications, suffice to provide superior performance (Wei et al., 2013; Lin and Bilmes, 2009; Lin et al., 2013).

By Lemma 5, \( f^\text{fac} \) alone provides a good approximation for \( f^\text{fac} \). It thus suffices, in this case, to apply a single-stage greedy algorithm (MULTIGREED with \( J = 1 \)) using \( f^\text{fac} \) as the surrogate. As a concrete example, consider an instance of the procedure with \( \theta = 0.05 \), \( n = 10^6 \), \( k = 0.009n \), and \( \ell = 0.1n \). Then, Lemma 5 implies that with probability 95%, \( f^\text{fac}(S) = f^\text{fac}(S) \) holds for any \( |S| \geq 0.00816n \), giving an individual greedy ratio of \( \alpha_i = 1 \) for \( 0.00186n \leq i \leq 0.1n \). The greedy ratio \( \alpha \), defined as the harmonic mean of \( \{\alpha_i\}_{i=1}^n \), is then bounded as \( \alpha \leq 1.02 \), which guarantees a solution in this instance close to optimum, thanks to Theorem 1.

**Saturated coverage function:** Successfully applied in document summarization (Lin and Bilmes, 2011), the saturated coverage function is another subclass of graph-based submodular functions. However, the class of facility location functions, for various applications, suffice to provide superior performance (Wei et al., 2013; Lin and Bilmes, 2009; Lin et al., 2013).

A main intuition of this result, is that \( f^\text{sat} \) is modular up to set of size \( \ell_1 \). Hence it makes sense to use \( f^\text{mod} \) for these cases. Similarly for the second stage, it is reasonable to use \( f^\text{sub} \) with an appropriate \( p \).

**Feature based submodular function:** Successfully applied in the speech data subset selection problem (Wei et al., 2014a;b), the feature based submodular function has the following form:

\[
f^\text{fe} = \sum_{u \in F} g(c_u(S)),
\]

where \( g \) is concave in the form \( g(x) = x^a \) for \( 0 < a \leq 1 \), \( F \) is a set of “features”, and \( c_u(S) = \sum_{v \in S} c_u(v) \) is a non-negative modular score for feature \( u \in F \) in set \( S \), with \( c_u(v) \) measuring the degree to which item \( u \) possesses feature \( u \). Maximizing this objective naturally encourages diversity and coverage of the features within the chosen set of items. Again, \( f^\text{fe} \) is a member of the class of uniform submodular mixtures. The curvature of \( f^\text{fe} \) is governed by the curvature of the concave function \( g \) and thus is determined by \( a \). We can construct a two-stage procedure similar to that for \( f^\text{sat} \), where we optimize over \( f^\text{mod} \) and \( f^\text{sub} \) with a suitable choice of the sampling probability \( p \).

**Lemma 7:** Given the feature based submodular function, an instance of MULTIGREED with the size constraints being \( \ell_1 \) and \( \ell_2 \), yields a solution with the individual greedy ratio bounded as:

\[
1 \leq \alpha_i \leq O(1^{-a}), \text{ for } i = 1, \ldots, \ell_1
\]

And with probability \( 1 - \delta \),

\[
1 \leq \alpha_i \leq \frac{1}{1 - \epsilon}, \text{ for } i = \ell_1 + 1, \ldots, \ell
\]

where \( \delta = \left( 1 - 5^\epsilon e^{-\frac{\epsilon (a+1)^2}{\epsilon (a+1)^2}} \right) \) and \( g^\ell = \max_{u \in V \setminus S_{\ell-1}} f(u | S_{\ell-1}) > 0 \).

The lemma implies that with an appropriate choice of the sampling probability \( p \) for \( f^\text{sub} \), the performance loss in the second stage could be negligible. However, there is some performance loss introduced by the first stage, depending on \( a \) and \( \ell_1 \). The choices for \( \ell_1 \) and \( \ell_2 \) determine the tradeoff between loss of the performance guarantee and the computational reduction: larger \( \ell_1 \) is chosen when computation is critical or when \( g \) is less curved (larger values of \( a \)), while larger \( \ell_2 \) is chosen when algorithmic performance is the priority or \( g \) is more curved (smaller values of \( a \)).

**Set cover function:** Another important class of submodular functions is the set cover function. Given a set of sets \( \{A_1, \ldots, A_{|V|}\} \), the universe \( U = \cup_{v \in V} A_v \), and the weights \( w : U \to \mathbb{R} \), the set cover function is defined as:

\[
f^\text{sc}(S) = w(\cup_{v \in S} A_v),
\]

where \( g \) is concave in the form \( g(x) = x^a \) for \( 0 < a \leq 1 \), \( F \) is a set of “features”, and \( c_u(S) = \sum_{v \in S} c_u(v) \) is a non-negative modular score for feature \( u \in F \) in set \( S \), with \( c_u(v) \) measuring the degree to which item \( u \) possesses feature \( u \). Maximizing this objective naturally encourages diversity and coverage of the features within the chosen set of items. Again, \( f^\text{fe} \) is a member of the class of uniform submodular mixtures. The curvature of \( f^\text{fe} \) is governed by the curvature of the concave function \( g \) and thus is determined by \( a \). We can construct a two-stage procedure similar to that for \( f^\text{sat} \), where we optimize over \( f^\text{mod} \) and \( f^\text{sub} \) with a suitable choice of the sampling probability \( p \).
where \( w(A) = \sum_{u \in A} w(u) \) for \( A \subseteq U \) with \( w(u) \) being the weight of item \( u \in U \). \( f_{SC} \) is again a uniform submodular mixture since it can be equivalently written as
\[
f_{SC}(S) = \sum_{u \in U} \min\{c_u(S), 1\}w(u),
\]
where \( c_u(S) \) denotes the number of times that item \( u \in U \) is covered by the set of sets \( \{A_v : v \in S\} \). Thanks to Lemma 3, a single-stage procedure where we optimize over the sampling based surrogate \( \hat{f}_{sub} \) with appropriate sampling probability \( p \), suffices to provide a good performance guarantee along with a computational reduction.

**Lemma 8.** Given a set cover function \( f_{SC} \), such an instance of MULTIGREED with the size constraints being \( \ell_1 = \ell \) yields a solution with the individual greedy ratio bounded as the following:

\[
1 \leq \alpha_i \leq \frac{1}{1 - \epsilon}, \quad \text{for } i = 1, \ldots, \ell
\]

where \( \epsilon = (1 - 5n\ell e^{-\frac{np_g(1/2)^2}{64n^4}}) \) and \( g^\ell = \max_{u \in V \setminus S_{\ell-1}} f(u|S_{\ell-1}) > 0 \).

6 Experiments

We empirically test the performance of MULTIGREED for three of the submodular functions considered above. We address the following questions: 1) how well does MULTIGREED perform compared to LAZYGREED, 2) how much relative time reduction can be achieved, 3) how well does the greedy ratio perform as a quality measure, 4) how well does the framework scale to massive data sets. We run experiments on two scenarios: 1) simulations with medium sized data, 2) real world speech data selection on millions of ground elements.

**Simulations:** All simulations are performed on the same data with size \( |V| = 20,000 \), formed by randomly sampling from a large speech recognition training corpus (the “Fisher” corpus). Each sample pair has a similarity score, and the graph-based submodular functions \( f_{Fac} \) and \( f_{Sat} \) are instantiated using the corresponding similarity matrix. A set of features \( F \) sized \( |F| \approx 75000 \) is derived from the same data to instantiate \( f_{Fac} \). In all runs of MULTIGREED, we set \( \{\beta_i\}_{i=1}^{\ell} \) using the schedule \( \beta_i = c + \frac{(1-i)(1-c)}{\ell} \) with \( c = 0.5 \). Performance of MULTIGREED and LAZYGREED is measured by the function valuations and the wall-clock running time. The optional stage of pruning is performed only for \( f_{Fac} \), but not for \( f_{Fac} \), since both \( f_{Fac} \) and \( f_{Sat} \) are very curved functions, for which the pruning procedure cannot effectively remove items.

![Figure 1](image1.png)

**Table 1.** Word error rates under averaged random, histogram-entropy, and the multi-stage submodular chosen subsets at various sized percentages (lower the better).

</table>

For \( f_{Fac} \), we use one stage with surrogates \( f_{k}\)(-NNG) with \( k \in \{50, 100, 200, 300\} \). MULTIGREED gives about a 20-80 times speedup over LAZYGREED with at least 99.8\% of the standard greedy solution (first column of Fig. 1). For \( f_{Sat} \), the saturation ratio \( \xi \) is set as 0.25. Two stages using surrogate functions \( f_{mod} \) and \( f_{sub} \) are applied, under size constraints \( \ell_1 = \lfloor \frac{n^2}{(4-\xi)(1+\xi)} \rfloor = 0.05n \), and \( \ell_2 = \ell - \ell_1 \). We test \( f_{sub} \) with various sampling probabilities: \( p \in \{0.25\%, 0.5\%, 1\%, 1.5\%\} \). The results (2nd column of Fig. 1) show a speedup of up to 250 with at least 99.25\% the quality of LAZYGREED. Next, for \( f_{Sat} \), we set \( g \) to be the square root function. Two stages of surrogates \( f_{mod} \) and \( f_{sub} \) are applied. \( f_{sub} \) is defined on a randomly selected feature subset size of 37,500. We test with different combinations of size constraints \( \ell_1 \) and \( \ell_2 \) by setting \( \ell_1 \in \{0, 0.25\ell, 0.5\ell, 0.75\ell\} \) with \( \ell_2 = \ell - \ell_1 \). This gives about a 2-8 times speedup with at least 99.3\% of LAZYGREED quality (right column of Fig 1). Empirically, the greedy ratio is very tight since it is always close to 1. For most cases, it is a good indicator of the performance for
function valuations, since lower values of \( \alpha \) always lead to higher performance of MultGreed. For \( f_{\text{fac}} \) and \( f_{\text{sat}} \), the speedup reported does not include the potentially significant additional complexity reduction on graph-construction. Especially for \( f_{\text{fac}} \), efficient algorithms exist for fast (approximate) construction of the \( k \)-NNG (Beygelzimer et al., 2006).

**Speech Data Subset Selection:** We next test the performance of MultGreed on a very large-scale problem, where running even LazyGreed is infeasible. We address the problem of speech data subset selection (King et al., 2005; Lin and Bilmes, 2009; Wei et al., 2013): given a massive (speech) data set for training automatic speech recognition (ASR) systems, we wish to select a representative subset that fits a given budget (measured in total time) and train a system only on the subset. The intended benefit is to significantly shorten ASR system development time, which is then only done on the representative subset of the data. Problem 5 addresses this where the objective is the facility location function \( f_{\text{fac}} \), and the pair-wise similarity between speech samples is computed by kernels (Wei et al., 2013). We subselect 1,322,108 segments of speech (i.e., \( |V| = n = 1,322,018 \)). The estimated running time of LazyGreed with \( f_{\text{fac}} \) on such large data is at least a week. Rendering the full \( O(n^2) \) similarity matrix is even more impractical due to memory requirements.

We here test MultGreed using \( f_{\text{fac}} \) with the sparsity of \( k \)-NNG set as \( k = 1,000 \). MultGreed, then, runs in only a few minutes, yielding a speedup of more than a thousand over LazyGreed! We measure the performance of the selection by the word error rate (WER) of the ASR system trained on the corresponding selected subset of the data. We test on different budget constraints (5%, 10% and 20% of the whole speech data). We compare our selection against two baseline selection methods: (1) averaged random method, where we randomly sample the data set at appropriate sizes, train different ASR systems for each set, and average their WER; (2) a non-submodular “histogram-entropy” based method, described in (Wu et al., 2007). Table 1 illustrates that our framework yields consistently superior results to these baselines.

7 Discussion

Certain other domains may be applicable to the analysis introduced in this paper. In the case of feature selection, for example, one may wish to optimize the mutual information function \( f_{\text{mi}} = I(X_S;C) \) which either is not submodular, or can become submodular by assuming that the random variables \( X_v \) are independent given \( C \) (Krause and Guestrin, 2005a). In either case, however, the complexity of evaluating \( f_{\text{mi}} \) can be daunting, leading to previous work suggesting a tractable surrogate

\[
\hat{f}_{\text{mi}}(S) = \sum_{v \in S} I(X_v;C) - \lambda \sum_{u,v \in S} I(X_v;X_u)
\]

where \( \lambda \) is a hyperparameter (Peng et al., 2005). Under certain assumptions, this surrogate is in fact equivalent to the original (Balagani and Phoha, 2010). Unnoticed by these authors, however, this function is submodular and non-monotone. We plan in the future to extend our framework to additionally handle such functions.

We would also like to extend these ideas to other submodular optimization scenarios, like submodular minimization (Fujishige and Isotani, 2011; Iyer et al., 2013a;b), and the class of optimization problems involving submodular constraints (Iyer and Bilmes, 2013) (which includes the submodular set cover, the submodular cost submodular set cover, and the submodular cost submodular knapsack). While many of the algorithms for these problems use proxy functions as surrogates, they often choose generic functions as proxies to obtain theoretical guarantees. It will be interesting to see if an intelligent design of surrogate functions, could yield better theoretical guarantees for real world problems.

Appendix

Proof of Lemma 1

Proof. Let \( s_1, \ldots, s_\ell \) be the sequence of items selected by an instance of the LazyGreed. We denote that \( S_i = \{s_1, \ldots, s_i\} \), such that \( S_1 \subset S_2 \subset \cdots \subset S_\ell \). Consider the sequence of items \( \{u_1, \ldots, u_n\} \) ordered non-increasingly in terms of their gain conditioned on all other items, i.e., \( f(u_1|V \setminus u_1) \geq \cdots \geq f(u_n|V \setminus u_n) \). Without loss of generality, we assume that \( S_\ell \neq \{u_1, \ldots, u_\ell\} \), otherwise, the Lemma follows trivially.

Next, we show the following:

\[
   f(s_i|S_{i-1}) \geq f(u_i|V \setminus u_i), \forall i = 1, \ldots, \ell. \tag{21}
\]

We consider two cases:

---

Let \( s_1, \ldots, s_\ell \) be the sequence of items selected by an instance of the LazyGreed. We denote that \( S_i = \{s_1, \ldots, s_i\} \), such that \( S_1 \subset S_2 \subset \cdots \subset S_\ell \). Consider the sequence of items \( \{u_1, \ldots, u_n\} \) ordered non-increasingly in terms of their gain conditioned on all other items, i.e., \( f(u_1|V \setminus u_1) \geq \cdots \geq f(u_n|V \setminus u_n) \). Without loss of generality, we assume that \( S_\ell \neq \{u_1, \ldots, u_\ell\} \), otherwise, the Lemma follows trivially.

Next, we show the following:

\[
   f(s_i|S_{i-1}) \geq f(u_i|V \setminus u_i), \forall i = 1, \ldots, \ell. \tag{21}
\]

We consider two cases:
Consider the following:
\[
\begin{align*}
    f(s_i|S_{i-1}) &= \max_{v \in V} f(v|S_{i-1}) \\
    &\geq f(u_i|S_{i-1}) \\
    &\geq f(u_i|V \setminus u_i)
\end{align*}
\]

For items \( j \in V \setminus \hat{V} \), the singleton gain can be bounded as the following:

\[
f(j) < f(u_i|V \setminus u_i) \leq f(s_i|S_{i-1})
\]

The singleton gain of the items in the removed data set is strictly less than smallest the marginal gain of the selected item by the greedy algorithm, hence, it is guaranteed that the greedy selection does not pick items from \( V \setminus \hat{V} \), hence the pruning procedure does not affect the performance of the standard greedy procedure. \( \square \)

**Proof of Theorem 1**

**Proof.** We employ similar proof techniques from (Conforti and Cornuejols, 1984), where they show the curvature dependent bound for Problem 1. We generalize their results by introducing the greedy ratio in the bound.

To prove the theorem, we need the following two Lemmas.

**Lemma 9.**

\[
\prod_{i=1}^{n}(1-\frac{1}{x_i}) \leq (1-\frac{1}{\bar{x}_h})^n
\]  

where \( x_i \geq 1, \forall i = 1, \ldots, n \), and \( \bar{x}_h \) is harmonic mean of \( x_i \)’s, i.e., \( \bar{x}_h = \frac{n}{\sum_{i=1}^{n} \frac{1}{x_i}} \).

**Proof.** Consider the fact that geometric mean of any non-negative vector lower bounds arithmetic mean of the same vector, namely,

\[
\left( \prod_{i=1}^{n} z_i \right)^{1/n} \leq \frac{\sum_{i=1}^{n} z_i}{n}
\]

where \( z_i \geq 0, \forall i \).

Let \( z_i = 1 - \frac{1}{x_i} \), where \( x_i \geq 1 \), we have

\[
\left( \prod_{i=1}^{n} (1-\frac{1}{x_i}) \right)^{1/n} \leq \frac{\sum_{i=1}^{n} (1-\frac{1}{x_i})}{n}
\]  

(24)

Then,

\[
\prod_{i=1}^{n} (1-\frac{1}{x_i}) \leq \left( \frac{\sum_{i=1}^{n} (1-\frac{1}{x_i})}{n} \right)^n
\]  

(25)

Rearrange the term in the R.H.S,

\[
\sum_{i=1}^{n} (1-\frac{1}{x_i}) = 1 - \frac{\sum_{i=1}^{n} \frac{1}{x_i}}{n}
\]  

(26)

\[
= 1 - \frac{1}{\sum_{i=1}^{n} \frac{1}{x_i}}
\]  

(27)

\[
= 1 - \frac{1}{\bar{x}_h}
\]  

(28)

**Lemma 10.** For \( t = 0, \ldots, \ell - 1 \),

\[
\sum_{i,s_t \in S^t \cap S^{t-1}} f(s_t|S^{t-1}) + \kappa f_{t+1} \sum_{i,s_t \in S^t \cap S^{t-1}} f(s_t|S^{t-1}) + \alpha_{t+1} (\ell - |S^t \cap S^{t-1}|) f(s_{t+1}|S^t) \geq f(S^{t+1})
\]

where \( S^t = \{s_1, \ldots, s_t \} \), \( \ell \) is the size constraint, \( \kappa f \) is the total curvature of \( f \), and \( \alpha_t \) is the individual greedy ratio for iteration \( t \).

**Proof.** By submodularity and definition of the greedy ratio, we have the following inequality:

\[
f(S^{OPT} \cup S^t) \leq f(S^t) + \sum_{u \in S^{OPT} \setminus S^t} f(u|S^t)
\]  

(29)

\[
\leq f(S^t) + \sum_{u \in S^{OPT} \setminus S^t} \alpha_{t+1} f(s_{t+1}|S^t)
\]  

(30)

\[
= f(S^t) + |S^{OPT} \setminus S^t| \alpha_{t+1} f(s_{t+1}|S^t)
\]  

(31)

By the definition of curvature, we have

\[
f(S^{OPT} \cup S^t)
\]  

(32)

(33)

\[
\geq f(S^{OPT}) + (1-\kappa f) \sum_{i,s_t \in S^t \cap S^{t-1}} f(s_t|S^{t-1})
\]  

(34)

Combining inequalities 31 and 34, we can get the following bound:

\[
f(S^{OPT}) + (1-\kappa f) \sum_{i,s_t \in S^t \cap S^{t-1}} f(s_t|S^{t-1})
\]  

\[
\leq f(S^t) + |S^{OPT} \setminus S^t| \alpha_{t+1} f(s_{t+1}|S^t)
\]
We start with the case where $m = 1$. For notation simplicity we write $\mathbf{S} = S^1$. Then, if $\rho \in \mathbf{S}$ is an optimum to the linear program. Hence, $\rho$ is a solution to the optimization problem: for any $i$, equivalently $\frac{\rho_i}{\rho_i^*} \leq 1$. Consider the following for $i = p, \ldots, \ell$:

$$\frac{\rho_i}{\rho_i^*} = \frac{\ell - 1}{\ell} \prod_{j=p+1}^{\ell - 1} \frac{1 - \frac{\kappa}{(\ell - j) \alpha_j}}{1 - \frac{\kappa}{(\ell - 1) \alpha_j}} \leq \frac{\ell - 1}{\ell} \prod_{j=p+1}^{\ell} \frac{1}{1 - \frac{\kappa}{(\ell - 1) \alpha_j}} \leq \frac{(1 - \frac{\kappa}{\ell})^{\ell - 1} - 1}{(1 - \frac{\kappa}{\ell})^{\ell - 2} - 2} \leq 1$$

The first inequality follows since $\frac{1 - \frac{\kappa}{\ell}}{1 - \frac{\kappa}{\ell}}$ is monotonically increasing with $\alpha$, hence, its maximum is attained when $\alpha = 1$. The last inequality holds from the fact that $(1 - \frac{\kappa}{\ell})^{\ell - 1}$, which is monotonically increasing when $x \geq 1$. We have shown that $\rho_i \leq \rho_i^*$ for any $i$, hence, $B(\emptyset) \leq B(p)$. We are going to show that $B(i_1, \ldots, i_m) \geq B(\emptyset)$ by induction. It’s already proved that it holds when $m = 1$. Suppose $B(i_1, \ldots, i_q) \geq B(\emptyset)$ holds, we wish to show the following: $B(i_1, \ldots, i_q, i_{q+1}) \geq B(i_1, \ldots, i_q)$ for any $i_{q+1} \notin \{i_1, \ldots, i_q\}$. We denote the solution to the problem $B(i_1, \ldots, i_q)$ as $\rho_i^B_q$, and the solution to the problem $B(i_1, \ldots, i_q, i_{q+1})$ as $\rho_i^B_{q+1}$. It’s easy to see that $\rho_i^B_{q+1} = \rho_i^B_q$, for $i = 1, \ldots, i_{q+1}$. Let $r = i_{q+1}$, then for $i = r + 1, \ldots, \ell$, we have the following:

$$\frac{\rho_i^B_q}{\rho_i^B_{q+1}} = \frac{1}{(\ell - q) \alpha_r} \prod_{j=r+1}^{\ell - 1} \frac{1 - \frac{\kappa}{(\ell - j) \alpha_j}}{1 - \frac{\kappa}{(\ell - q - 1) \alpha_j}} \leq \frac{(1 - \frac{\kappa}{q})^{q - 1} - 1}{(1 - \frac{\kappa}{q - 1})^{q - 2}} \leq 1$$

Therefore, we have $\rho_i^B_q \leq \rho_i^B_{q+1}$ for all $i$, thus $B(i_1, \ldots, i_q) \leq B(i_1, \ldots, i_{q+1})$.

Then, we have the following:

$$\frac{f(S^\ell)}{f(S^{\text{OPT}})} \geq \sum_{i: x_i \in \mathbf{S} \setminus \mathbf{S}^{\text{OPT}}} f(x_i)$$

To show that $B(p) \geq B(\emptyset)$, it suffices to show that $\rho_i \leq \rho_i^*$ for any $i$, equivalently $\frac{\rho_i}{\rho_i^*} \leq 1$. Consider the following for $i = p, \ldots, \ell$:

$$\frac{\rho_i}{\rho_i^*} = \frac{\ell - 1}{\ell} \prod_{j=p+1}^{\ell - 1} \frac{1 - \frac{\kappa}{(\ell - j) \alpha_j}}{1 - \frac{\kappa}{(\ell - 1) \alpha_j}} \leq \frac{\ell - 1}{\ell} \prod_{j=p+1}^{\ell} \frac{1 - \frac{\kappa}{(\ell - 1) \alpha_j}}{1 - \frac{\kappa}{(\ell - 1) \alpha_j}} \leq \frac{(1 - \frac{\kappa}{\ell})^{\ell - 1} - 1}{(1 - \frac{\kappa}{\ell})^{\ell - 2} - 2} \leq 1$$

The first inequality follows since $\frac{1 - \frac{\kappa}{\ell}}{1 - \frac{\kappa}{\ell}}$ is monotonically increasing with $\alpha$, hence, its maximum is attained when $\alpha = 1$. The last inequality holds from the fact that $(1 - \frac{\kappa}{\ell})^{\ell - 1}$, which is monotonically increasing when $x \geq 1$. We have shown that $\rho_i \leq \rho_i^*$ for any $i$, hence, $B(\emptyset) \leq B(p)$. We are going to show that $B(i_1, \ldots, i_m) \geq B(\emptyset)$ by induction. It’s already proved that it holds when $m = 1$. Suppose $B(i_1, \ldots, i_q) \geq B(\emptyset)$ holds, we wish to show the following: $B(i_1, \ldots, i_q, i_{q+1}) \geq B(i_1, \ldots, i_q)$ for any $i_{q+1} \notin \{i_1, \ldots, i_q\}$. We denote the solution to the problem $B(i_1, \ldots, i_q)$ as $\rho_i^B_q$, and the solution to the problem $B(i_1, \ldots, i_q, i_{q+1})$ as $\rho_i^B_{q+1}$. It’s easy to see that $\rho_i^B_{q+1} = \rho_i^B_q$, for $i = 1, \ldots, i_{q+1}$. Let $r = i_{q+1}$, then for $i = r + 1, \ldots, \ell$, we have the following:

$$\frac{\rho_i^B_q}{\rho_i^B_{q+1}} = \frac{1}{(\ell - q) \alpha_r} \prod_{j=r+1}^{\ell - 1} \frac{1 - \frac{\kappa}{(\ell - j) \alpha_j}}{1 - \frac{\kappa}{(\ell - q - 1) \alpha_j}} \leq \frac{(1 - \frac{\kappa}{q})^{q - 1} - 1}{(1 - \frac{\kappa}{q - 1})^{q - 2}} \leq 1$$

Therefore, we have $\rho_i^B_q \leq \rho_i^B_{q+1}$ for all $i$, thus $B(i_1, \ldots, i_q) \leq B(i_1, \ldots, i_{q+1})$.
where $\alpha$ is the harmonic mean of $\alpha_i$’s.

To show that the approximation factor is tight. We only show for the case where $\kappa = 1$. Results could be generalized for any value of $\kappa$.

We use the similar tight instance construction as in (Nemhauser and Wolsey, 1978), where they show a class of instances of the greedy algorithm that achieves the approximate factor $(1 - (1 - \frac{1}{2})^\ell)$. In this case, we are going to show an instance of MULTIGREED that achieves the approximate factor $(1 - (1 - \frac{1}{2\alpha})^\ell)$, where $\alpha$ is the greedy ratio of this instance of MULTIGREED. To this end, let’s define a family of submodular functions that provide worst-case examples over all possible $\alpha \geq 1$ and $\ell$. The $(\alpha, \ell)$th subfamily is specified by function $g_{\alpha,\ell}$. Notice that $g_{\alpha,\ell}$ is a set function on a ground set $V$ of cardinality $n$. For notation simplicity, we drop the dependency on $n$ in the set function $g_{\alpha,\ell}$, although there is a different function for each $n$. We will show how to construct a submodular function for a combination of $n, \alpha, \ell$, on which MULTIGREED achieves the approximation factor $(1 - (1 - \frac{1}{\alpha\ell})^\ell)$.

Consider ground set $V = \{1, 2, \ldots, n\}$ that contains two types of elements special and plain. The subset $M$, with $|M| = \ell$, is the set of special elements and $V \setminus M$ is the set of plain elements. Value of $g_{\alpha,\ell}(S), S \subseteq V$, depends only on $|S|, |S \cap M|, \alpha$ and $\ell$. For this reason, we write $g_{\alpha,\ell}(S) = g_{\alpha,\ell}(|S \cap M|, |S|) = g_{\alpha,\ell}(i, j)$, where $i = |S \cap M|$ and $j = |S|, i = 0, \ldots, \min(j, \ell), j = 0, \ldots, n$. Let $g_{\alpha,\ell}(i, j)$ for general $\ell, \alpha, i, j$ be defined as following:

\begin{align*}
g_{\alpha,\ell}(0, j) &= \ell(1 - (1 - \frac{1}{\alpha\ell})^j), 0 \leq j \leq n; \quad (46) \\
g_{\alpha,\ell}(i, j) &= g_{\alpha,\ell}(0, j-i) + i \frac{\ell - g_{\alpha,\ell}(0, j-i)}{\ell}, \quad (47) \\
& \text{for } 1 \leq i \leq \ell, i \leq j \leq n; \quad (48)
\end{align*}

The fact that $g_{\alpha,\ell}$ is monotone submodular is proved by tedious enumeration of the definition of submodularity and monotonicity case by case. We leave out the proof here and defer readers to (Nemhauser and Wolsey, 1978) for detail. Consider an instance of MULTIGREED performed on $g_{\alpha,\ell}$, that only choose items from $V \setminus M$. Then, the greedy ratio would be:

$$\alpha_i = \max_{u \in V} \frac{f(u|S_{i-1})}{f(s_i|S_{i-1})} = \frac{g_{\alpha,\ell}(1, i) - g_{\alpha,\ell}(0, i-1)}{g_{\alpha,\ell}(0, i) - g_{\alpha,\ell}(0, i-1)} = \frac{\alpha}{1 - \alpha}$$. \quad (49)

Hence, the harmonic mean of $\alpha_i$’s is equal to $\alpha$. Output subset of MULTIGREED is a subset of $V \setminus M$ with cardinality $\ell$, thus has function value $g_{\alpha,\ell}(0, \ell) = \ell(1 - (1 - \frac{1}{\alpha\ell})^\ell)$, while optimal subset that maximizes submodular function $f$ under cardinality constraint $\ell$ should be $M$ and has function value $g_{\alpha,\ell}(M) = g_{\alpha,\ell}(\ell, \ell) = \ell$. Approximation factor becomes $\frac{g_{\alpha,\ell}(0, \ell)}{g_{\alpha,\ell}(M)} = 1 - (1 - \frac{1}{\alpha\ell})^\ell$. Therefore, the bound in terms of the greedy ratio $\alpha$ is tight.

**Proof of Theorem 2**

**Proof.** Following the similar proof techniques from (Nemhauser et al., 1978) along with the definition of the knapsack greedy ratio in Eqn 6, we have the following:

$$f(S_{\text{OPT}}) \leq \frac{\alpha B}{c(s_i)} f(s_i|S_{i-1}) + f(S_{i-1}), \forall i = 1, \ldots, N \quad (50)$$

Rearrange the inequality, we get the following:

$$f(S_{i}) - f(S_{i-1}) \leq (1 - \frac{c(s_i)}{\alpha B}) (f(S_{\text{OPT}}) - f(S_{i-1}))$$

holds for $i = 1, \ldots, N$. Then, we can obtain the following:

$$f(S_N) \geq (1 - \prod_{i=1}^{N} (1 - \frac{c(s_i)}{\alpha B})) f(S_{\text{OPT}})$$

By definition of the knapsack greedy ratio in Eqn 7 and Lemma 9, we obtain the following:

$$f(S_N) \geq (1 - \frac{B'}{\alpha BN})^N f(S_{\text{OPT}})$$

$$\geq (1 - e^{-\frac{B'}{\alpha B N}}) f(S_{\text{OPT}})$$

$$\geq (1 - e^{-\frac{1}{\alpha}}) f(S_{\text{OPT}})$$

Since $S_N$ is not a feasible solution to Problem 5, but $S_{N-1}$ is. The knapsack greedy algorithm compares the solution between $S_{N-1}$ and the maximum single value $f(v^*)$, where $v^* \in \text{argmax}_{u \in V: c(u) \leq B} f(u)$, and outputs the maximum of the two. Then, we can bound the output solution as follows:

$$\max\{f(v^*), f(S_{N-1})\} \geq \frac{1}{2} (f(v^*) + f(S_{N-1}))$$

$$\geq \frac{1}{2} (f(s_N) + f(S_{N-1}))$$

$$\geq \frac{1}{2} f(S_N)$$

$$\geq \frac{1}{2} (1 - e^{-\frac{1}{\alpha}}) f(S_{\text{OPT}})$$

**Proof of Theorem 3**

This Theorem immediately follows from Theorem 2 and Theorem 3.1 of (Iyer and Bilmes, 2013).

**Proof of Lemma 3**

**Proof.** We employ methods that are similarly presented in (Mirzasoleiman et al., 2013), where they show the
theoretical guarantee of applying \( \hat{f}_{\text{sub}} \) as a surrogate function for the class of decomposable submodular functions. For notation simplicity, we write \( \hat{f}_{\text{sub}} \) as \( \hat{f} \). We denote the ground set size to be \( |V| = n \). The expected size of the subset \( T' \subseteq T \) is \( np \). We are going to show that \( \hat{f} \) is close to the target function \( f \) for all possible subset \( S \) of size \( |S| \leq \ell \) with high probability, where \( \ell \) is the size constraint of the selection. Given a fixed \( S \subseteq V \), we can treat all \( f_i(S) \)'s as independent random variables and, by assumption, they are bounded as \( \leq f_i(S) \leq B \).

By Chernoff bound, we can bound the probability \( \Pr(|\hat{f}(S) - \mu| \geq \epsilon) \leq 2e^{-n\epsilon^2 \mu^2} \). By the Hoeffding inequality, we can bound the probability \( \Pr(|\hat{f}(S) - \mu| \geq \epsilon) \leq 2e^{-\frac{2\epsilon^2}{2\mu^2}} \) and \( \Pr(|\hat{f}(S) - \mu| \geq \epsilon) \leq 2e^{-\frac{1}{10\mu^2}} \), where \( \mu \) is the mean of the random variable \( f_i(S) \) for any \( i \).

By union bound, we have the following for \( \epsilon \) being small such that \( \frac{1}{10\mu^2} \leq \frac{1}{2} \).

\[
\Pr(|\hat{f}(S) - \hat{f}(S)| \leq 2\epsilon) \geq 1 - 2e^{-2n\epsilon^2} - 2e^{-\frac{2\epsilon^2}{10\mu^2}} - e^{-\frac{1}{20\mu^2}} \\
\geq 1 - 5e^{-\frac{2n\epsilon^2}{10\mu^2}}
\]

There are in total \( n^{\ell} \) sets of size less or equal to \( \ell \). By the union bound again, we can have the following:

\[
\Pr(|\hat{f}(S) - \hat{f}(S)| \leq 2\epsilon, \forall S \subseteq V, |S| \leq \ell) \geq 1 - 5n^{\ell}e^{-\frac{2n\epsilon^2}{10\mu^2}}
\]

(51)

Notice that this bound is meaningful only when \( 1 - 5n^{\ell}e^{-\frac{2n\epsilon^2}{10\mu^2}} > 0 \), in other words, we can obtain meaningful theoretical guarantee when the ground set size \( n \) is sufficiently large.

Now, we can analyze the performance guarantee in terms of the greedy ratio. Continuing from the results in the inequality 51, we have that

\[
|f(j|S \setminus j) - \hat{f}(j|S \setminus j)| \leq 4\epsilon
\]

for any \( j \) in \( V \), and \( |S| \leq \ell \), with probability \( (1 - 5n^\ell e^{-\frac{2n\epsilon^2}{10\mu^2}}) \). Let the gain in the last iteration of the greedy algorithm to be \( g_i^f \), and assume that \( g_i^f > 0 \). Let \( t_i \) be the item that attains the maximum marginal gain by applying the target function \( f \) and \( s_i \) be the item selected by the surrogate function \( \hat{f} \) for iteration \( i \), then we have the following

\[
\alpha_i = \frac{f(t_i|S_{i-1})}{f(s_i|S_{i-1})} \leq \frac{f(t_i|S_{i-1})}{f(s_i|S_{i-1})} - 4\epsilon \leq \frac{f(t_i|S_{i-1})}{f(s_i|S_{i-1})} - 4\epsilon
\]

\[
\leq \frac{f(t_i|S_{i-1})}{f(t_i|S_{i-1})} - 8\epsilon = \frac{1 - 8\epsilon}{\epsilon_G} = \frac{1}{1 - \epsilon'}
\]

where \( \epsilon' = \frac{8\epsilon}{\epsilon_G} \). To formalize the result in terms of the greedy ratio, we can claim that with probability \( (1 - 5n^\ell e^{-\frac{2n\epsilon^2}{10\mu^2}}) \), we can bound the greedy ratio in each iteration as \( \alpha_i \leq \frac{1}{1 - \epsilon'} \).

**Proof of Lemma 4**

Proof. Let \( t_i \) be the item with maximum marginal gain in iteration \( i \), i.e., \( t_i \in \arg\max_{u \in V} f(u|S_{i-1}) \). By definition of the greedy ratio, we have the following:

\[
\alpha_i = \frac{f(t_i|S_{i-1})}{f(s_i|S_{i-1})} \leq \frac{f(t_i)}{f(s_i|S_{i-1})} \leq \frac{f(s_i)}{f(s_i|S_{i-1})}
\]

\[
\leq \frac{1}{1 - \kappa_f(S_{i-1})}
\]

The second inequality follows from that fact that \( s_i \) is the item greedily selected by the modular proxy \( \hat{f} \), therefore \( f(s_i) = \max_{u \in V \setminus S_{i-1}} f(u) \geq f(t_i) \).

The last inequality follows from the definition of the curvature.

**Proof of Lemma 5**

Proof. Let \( \tilde{w}_i \) be the \( i \)th row vector obtained from the \( k \)-NNG approximation from the full graph. Then, \( \tilde{w}_i \) is the approximate vector for \( w_i \) with only \( k \) largest values retained. The key observation for the facility location function is that \( \hat{f}_{\text{fac}}(S) = \hat{f}_{\text{fac}}^{k\text{-NNG}}(S) \), if the set \( S \) contains items that are among the top \( k \) values of the row vector \( \tilde{w}_i \) for all \( i \), since \( \max_{j \in S} \tilde{w}_i(j) = \max_{j \in S} \tilde{w}_i(j) \), if \( S \) contains items that are among the top \( k \) values of \( \tilde{w}_i \).

For notation simplicity, we write \( \hat{f} \) for \( \hat{f}_{\text{fac}}^{k\text{-NNG}} \) and \( f \) for \( f_{\text{fac}} \). For any item \( t \in V \), we have the probability of \( w_i, t \) not being among the top \( k \) elements of each row vector can be then computed as \( [1 - (\frac{n-k}{n})^m]^n \).

Let the probability that \( S_m \) covers among the top \( k \) elements of all row vectors be \( 1 - \theta \). Then, we have the following:

\[
[1 - (\frac{n-k}{n})^m]^n = 1 - \theta
\]

Simplify the equation, we can get the following:

\[
k = n[1 - (1 - (1 - \theta)^{\frac{1}{m}})^n]
\]

(52)

\[
n \approx n[1 - (1 - e^{-\frac{\theta}{n}})^{\frac{1}{m}}]
\]

(53)

\[
n \approx n[1 - (\frac{\theta}{n})^{\frac{1}{m}}]
\]

(54)
The first approximation follows since $(1 - \theta)\frac{1}{n} \approx e^{-\frac{1}{n}}$, for $\theta$ being close to 0. The second approximation follows from that $e^{-\frac{1}{n}} \approx 1 - \frac{1}{n}$, with $-\frac{1}{n} \approx 0$. \hfill \square

**Proof of Lemma 6**

**Proof.** The bound of the individual greedy ratio $\alpha_i$'s for $i = \ell_1 + 1, \ldots, \ell$ can be immediately derived from Lemma 3. Therefore, it is left to show that $\alpha_i = 1$ for $i = 1, \ldots, \ell_1$, which, by Lemma 4, is equivalently as to show that $\kappa_f(S) = 0$ for $|S| \leq \ell_1$. For notation simplicity, we write $f_{\text{sqrt}}$ as $f$. To show that $\kappa_f(S) = 0$, we can equivalently show that $f(S) = \sum_{j \in S} f(j)$ for any $S$ of size $|S| \leq \left\lfloor \frac{n\xi}{(1-\xi)\gamma + \xi} \right\rfloor$.

Consider the following for any $S \subseteq V$ such that $|S| \leq \left\lfloor \frac{n\xi}{(1-\xi)\gamma + \xi} \right\rfloor$:

$$\sum_{j \in V} w_{i,j} = \sum_{j \in S} w_{i,j} + \sum_{j \in V \setminus S} w_{i,j} \leq |S|\rho_{\text{max}} + (n - |S|)\rho_{\text{min}} = \frac{|S|\gamma + (n - |S|)}{1 + \frac{n}{(1-\xi)\gamma + \xi} - \frac{1}{(1-\xi)\gamma + \xi}} = \xi$$

Without loss of generality, we can assume that all $w_{i,j} > 0$ for any $j \in S$ and a given $i$, since the above holds as well for $S' = \{ j \in S | w_{i,j} > 0, \forall i \}$. Therefore, we have that $\sum_{j \in S} w_{i,j} \leq \xi \sum_{j \in V} w_{i,j}$ for all $i$. From which, we conclude that $\kappa_f(S) = 0$, for any $|S| \leq \left\lfloor \frac{n\xi}{(1-\xi)\gamma + \xi} \right\rfloor$. \hfill \square

**Proof of Lemma 7**

**Proof.** The bound of the individual greedy ratio $\alpha_i$'s for $i = \ell_1 + 1, \ldots, \ell$ can be immediately derived from Lemma 3. Therefore, it is left to show that $\alpha_i \leq O(i^{1-a})$ for $i = 1, \ldots, \ell_1$. For notation simplicity, we write $f_{\text{lea}}$ as $f$. Let $\rho_{\text{min}} = \min_{u \in F, v \in V : c_u(v) > 0} c_u(v)$ and $\rho_{\text{max}} = \max_{u \in F, v \in V} c_u(v)$. It suffices to show the following:

$$\alpha_i \leq \frac{1}{(1 + (i - 1)\gamma)^a - ((i - 1)\gamma)^a}$$

where $\gamma = \frac{\rho_{\text{max}}}{\rho_{\text{min}}}$. It is easy to verify that

$$\frac{1}{(1 + (i - 1)\gamma)^a - ((i - 1)\gamma)^a} = O(i^{1-a})$$

given $\gamma$ is a constant. Let $t_i$ denote the item with maximum marginal gain in iteration $i$, i.e., $t_i \in \argmax_{u \in V \setminus S_{i-1}} f(u|S_{i-1})$, and $s_i$ denote the item selected by using the modular proxy $f_{\text{mod}}$. Consider the following:

$$\alpha_i = \frac{f(t_i|S_{i-1})}{f(s_i|S_{i-1})} \leq \frac{f(t_i)}{f(s_i|S_{i-1})} \leq \frac{f(s_i)}{f(S_{i-1})}$$

$$= \frac{\sum_{j \in F} [f(s_i) ]^a}{\sum_{j \in F} [f(s_i) ]^a} \leq \frac{\sum_{j \in F} [f(s_i) ]^a}{\sum_{j \in F} [f(s_i) ]^a}$$

Let’s consider the following function:

$$h(x_1, \ldots, x_n) = \frac{\sum_{i=1}^n (x_i)^a}{(x_1 + C)^a - C^a}$$

where $C$ is a constant. The function $h()$ is symmetric about all its variables $x_1, \ldots, x_n$. Notice that the function $h()$ is not convex or concave in its variables. However, we still want to maximize the function over the vector $x$ within the range $[\rho_{\text{min}}, \rho_{\text{max}}]$ element-wisely. First, we easily see that $h$ evaluated at $x_1 = x_2 = \cdots = x_n$ ranges in $(1, \infty)$.

To maximize the function $h$, we can simply maximize the function $h$ over the subspace where $x_1 = \cdots = x_n$, since the maximum of $h$ can be achieved in the subspace $x_1 = \cdots = x_n$. To maximize $h$, we can equivalently maximize the function $h(x) = \frac{\rho_{\text{max}}^a}{\sqrt{x+\rho_{\text{max}}^2}-\sqrt{x}}$ for $x \in [\rho_{\text{min}}, \rho_{\text{max}}]$, and it’s easy to verify that the maximum is attained at $x = \rho_{\text{min}}$. Moving back to upper bounding the greedy ratio at the $i$th iteration, we can get the following:

$$\alpha_i \leq \frac{\rho_{\text{min}}^a}{[1 + (i - 1)\gamma]^a - [(i - 1)\gamma]^a}$$
